**Abstract**—Ranking algorithms in traditional search engines are powered by enormous training data sets that are meticulously engineered and curated by a centralized entity. Decentralized peer-to-peer (p2p) networks such as torrenting applications and Web3 protocols deliberately eschew centralized databases and computational architectures when designing services and features. As such, robust search-and-rank algorithms designed for such domains must be engineered specifically for decentralized networks, and must be lightweight enough to operate on consumer-grade personal devices such as a smartphone or laptop computer. We introduce G-Rank, an unsupervised ranking algorithm designed exclusively for decentralized networks. We demonstrate that accurate, relevant ranking results can be achieved in fully decentralized networks without any centralized data aggregation, feature engineering, or model training. Furthermore, we show that such results are obtainable with minimal data preprocessing and computational overhead, and can still return highly relevant local results even when a user’s device is disconnected from the network. G-Rank is highly modular in design, is not limited to categorical data, and can be implemented in a variety of domains with minimal modification. The results herein show that unsupervised ranking models designed for decentralized p2p networks are not only viable, but worthy of further research.

*Author’s note: the experiments performed herein are open-source and can be found on GitHub<sup>1</sup>.*

## I. INTRODUCTION

The problem of relevance ranking in information retrieval problems has been well-studied for decades, solutions for which have enabled users to query vast swathes of information on the World Wide Web and retrieve highly relevant results within milliseconds. Nascent search-and-rank techniques for web search culminated with PageRank in 1998 [1], directly leading to Google’s ascendant dominance in the web search domain. All such algorithms, however, depend upon ever-growing databases of mapped relations between various information sources and topics, requiring enormous computational power to deliver lightning-fast results directly to a user’s device. Therefore, these algorithms all depend upon highly centralized information architectures with thousands of skilled attendants dedicated to maintaining and improving system capabilities.

As such, typical ranking algorithms are wholly unsuited for deployment in decentralized information architectures such as peer-to-peer (p2p) file sharing networks (e.g. BitTorrent) and various Web3 applications. These networks are

overwhelmingly comprised of individual users where the maximum computational and storage capacity available to any search-and-rank algorithm is that of an individual’s desktop computer or mobile device. The success of many nascent applications built atop decentralized networks therefore depends upon the efficacy of novel search-and-rank schemes designed specifically for these domains. These algorithms must have a zero-server architecture, be lightweight enough to run on a cheap smartphone, and yet be robust enough to return highly relevant results to each individual user.

Furthermore, these algorithms must adhere to the ethos of these decentralized networks, which often emphasize user privacy and information security foremost among its tenets. Any ranking algorithm built in such a domain must therefore be able to function effectively utilizing data immediately available to a user of a p2p application, the majority of which is often the user’s own data. That is not to say that a ranking algorithm cannot be improved via the sharing of information between participants in such networks, but rather that the algorithm must be entirely self-sufficient and self-contained without any meaningful expectation of obtaining new information outside of the local device. As first proposed in [28], the concept of utilizing message-passing as a means to build a cohesive model in a distributed setting became a novel instrument in respecting user privacy by emphasizing local-first computational paradigms.

The concept of local-first software is not new [27], and privacy-preserving machine learning schemes such as encrypted machine learning [40][41] and federated machine learning [36][37][38][39] already exist, yet the problems of security, storage, and overhead persist. Unfortunately, most of these machine learning models are supervised which handicaps developers by requiring large amounts of high-quality training data to achieve meaningful results. Any model that can quickly retrieve relevant information, sufficiently rank the results, and deliver it to the user without the need for training the model before deployment would allow for p2p networks of any size to deliver meaningful search capabilities without needing to bootstrap the model first. Therefore, truly decentralized unsupervised ranking system sits at the forefront of p2p and Web3 communications development.

The rapid growth of p2p file-sharing networks around the turn of the new millennium led to a boom in research for search algorithms designed explicitly for such networks [3][4][5][9][10][11][14][17]. Many such algorithms

<sup>1</sup><https://www.github.com/awrgold/G-Rank>

attempted to recreate the efficacy of well-known existing search and rank algorithms such as PageRank, yet the number of publications had plateaued and begun to decline around the beginning of the past decade. The explosive growth of blockchain and Web3 technologies has influenced a new generation of developers designing for a more decentralized web experience. Decentralized search and rank algorithms that do not depend upon any centralized entity to function properly, are domain-independent, and can sufficiently replicate the performance of more centralized solutions are still nascent. We demonstrate that a simple, lightweight, and effective ranking algorithm can be deployed to p2p applications while achieving respectable results.

We introduce the unsupervised ranking algorithm G-Rank designed explicitly for ranking search results in a p2p torrent-based music streaming platform. The goal of this first validation experiment is to demonstrate the "correctness" of an unsupervised learn-to-rank (LTR) model in the context of a distributed p2p file sharing network. This model requires no training or bootstrapping to function, is capable of returning relevant results to users within the first few queries, and is not constrained by any dependence upon large datasets. G-Rank is demonstrably capable of ranking results in line with their global popularity, even though the model itself is unaware of the best possible ranking for any given query term. G-Rank will quickly approach and oftentimes reach the optimal global ranking, even if a user does not perform any queries themselves; as a network utilizing G-Rank grows in usership, new users will see highly relevant results even with their first query.

The rest of this paper is as follows. Section 2 expounds upon the problem of relevance ranking, namely supervised versus unsupervised methods. Section 3 details the implementation of the G-Rank algorithm, describing the clicklog structure and gossip-based information dissemination mechanism necessary for its functioning, as well as the experimentation and evaluation of the model. Section 4 explores the results of the experiments, comparing them to other ranking algorithms for both traditional as well as decentralized web applications. Section 5 concludes our work.

## II. PROBLEM DESCRIPTION

Learn-to-rank is a well-known and thoroughly-studied problem with myriad solutions achieving excellent results, yet many of the most well-known ranking algorithms are designed around centralized data aggregators and supervised training methods. Past research into ranking search results within p2p networks often utilize training, testing, and validation datasets [8][18][35][42], which besides the traditional pitfalls of supervised learning also constrain the ranking problem into an optimization problem. Furthermore, such supervised methods lack inherent "memory" such that they cannot retain information as they observe it; as such, they require large training sets in order to learn latent statistical representations of the information they are provided. Compiling relevant datasets and appropriate labels requires considerable effort, which historically has been performed

manually by humans and is infeasible for exceptionally large datasets. Automated labeling methods such as semi-supervised learning can speed up this process, but these methods have the drawback of imparting their own inherent bias into the constructed dataset [44][45]; therefore the difficulty of labeling data in a manual or semi-supervised manner grows faster relative to the increase in size of data.

Other solutions treat ranking as a recommendation prediction problem, where results are sorted by the predicted score [31][33][34][35]. Framing the ranking problem as a recommendation prediction problem also depends heavily on the manner in which users "score" items that they are recommended. Depending on the application, the manner in which scores are calculated heavily influences the behavior of the recommender. In the domain of e-commerce, an item purchased by a user may be assigned a higher score than an item said user has viewed multiple times but not purchased, even if the user feels that the viewed item is more relevant to them. Meanwhile, a music recommender may assign a higher score to a song that appears in multiple playlists of a specific user yet has fewer overall streaming plays than a song that does not appear in any playlist yet contains a significant number of streaming plays for that same user. As such, the scoring system must be thoughtfully designed for the specific recommendation algorithm and its domain.

With regards to distributed machine learning, federated machine learning has several drawbacks in this domain as well. Federated models are often less accurate due to their relative inability to capture the variance in the overall data throughout the network, as each model is iteratively fitted to a small subset of data. Federated learning techniques, as presented in [36][37][38][39], utilizes message passing to disseminate model parameters during training. This parameter-passing mechanism is often considered sufficient enough to obfuscate local data - affording some degree of user privacy - though such methods are insufficient to prevent determined adversaries from recreating input data [46]. That being said, any such supervised methods still face the issue of requiring training datasets which limits the scope of potential research due to inadequate training data availability and the infeasibility of synthesizing such datasets oneself. As such, unsupervised ranking algorithms that can approach the performance of supervised ranking methods may be better suited towards p2p domains, where a significant portion of software is open-source and user privacy is often given higher priority than for traditional web services. Significantly reduced overhead in algorithm implementation and maintenance, therefore, is a major benefit for p2p environments. Creating a search engine for a p2p domain that requires no training yet can converge towards an optimal ranking as if an error rate is being minimized in a supervised model would constitute a major development in p2p applications.

### A. Security Concerns in Decentralized Networks (BETTER TITLE?)

Machine learning models deployed in p2p networks are vulnerable to several specific attack vectors, namely sybil

and spam attacks, which can undermine model accuracy and efficacy (SOURCES). Such attacks are inherently difficult to thwart in any decentralized network setting. As shown in [6], even PageRank is not immune to sybil attacks and therefore also requires considerable adaptation to trustless p2p environments. As such, sybil attacks on decentralized machine learning models are critical vulnerabilities that require deliberate mitigation efforts during the design of the model, and even such mitigation efforts are imperfect [43]. Meanwhile, spam attacks in p2p networks are often broader in scope yet still pose significant risk to machine learning models whose efficacy depend upon the veracity of the data they are fed.

These threats are well-understood and a variety of methods to thwart such attacks exist [47][48][43], however many of these solutions are based on supervised learning and therefore suffer from the same issues mentioned previously, or require the aggregation of network traffic through centralized "coordinators," eroding the trustlessness of p2p networks. As such, unsupervised machine learning models that are robust enough to function in the midst of spam or sybil attacks are critical to the expansion of search, ranking, and recommendation models for the decentralized web.

### III. ARCHITECTURE OF G-RANK

The domain for the following experiments is a simulation of a hypothetical music sharing and streaming application built upon a torrent-based p2p network (e.g. BitTorrent). This music application allows users (A.K.A. "nodes" when referring to network architecture, or "peers" when referring to other users in the network) to query other peers for the contents of their library and download files to their device. Whenever a user issues a query, the user device appends the query and its associated results to a clicklog that is stored locally on the device. At various intervals, each device shares a portion of its local clicklog with a selection of other peers in the network via a gossip protocol (See Section 3B). When a user's device receives a gossip message containing updated clicklog information, the device appends the new information to the local clicklog to be used by the ranking model in future queries.

The unsupervised method detailed herein focuses on ranking query search results relative to one another, i.e. pairwise comparison across all potential results. Due to the fact that each node in the network contains only a small subset of total possible search results, it is highly unlikely that any one node attain perfect ranking results without the dissemination of local clicklog information to other nodes in the network. Such a mechanism - be it via gossip, broadcasting search history, or a centralized information aggregation scheme - directly and heavily influences the behavior of the unsupervised ranking model. The continuous updating of data accessible to G-Rank is an example of continuous learning [13], where the model requires no re-training as each new data point becomes available. Instead, as each gossip message is received G-Rank considers this new information in real time, affording it the ability to continuously adapt to an ever-changing

Fig. 1. Users in the decentralized network may gossip irregularly, and not all nodes in the network may be recipients of a specific gossip message. (I honestly dunno wtf to do with this graphic, it seems so basic and we already talked about speaking at a higher, more "thesis-worthy" level. Also I could invert the pentagram if we wanted to go a more "demonic" route...)

environment with zero human intervention. Therefore, the ranking model's dependence upon the clicklog dissemination scheme is closely investigated alongside the actual performance of the ranking model, where various dissemination patterns and parameters are considered alongside ranking model parameters and functionality.

#### A. Unsupervised Ranking Model

When a user searches for a query term, the ultimate goal is to provide the most accurate list of results ranked by relevance to the query term as well as the user. First, the model checks the local clicklog for previous queries of a query term, and if this term has never been queried before it then searches for matches of this term in the metadata of local files stored in the music app, which includes title, artist, and genre tags. The model does not consider misspellings/typos, although methods such as those mentioned in [3] are highly effective at correcting for typos in information retrieval (IR) schemes and could potentially be integrated with G-Rank. If the query term has been seen before, it returns the most popular results for this query weighted by the similarity of search and click behavior of other users who have also issued similar or identical queries (as described in Section 3D).

Due to the fact that the search mechanism considers only the clicklog and item metadata, it is extremely unlikely that a item should erroneously become popularly associated with a query term that has no direct match with any of the item's metadata. The only situation in which this could arise is if a query term has never been seen before nor is contained in any accessible metadata. Should this happen, the search engine returns a list of popular items that have appeared recently in the user's local clicklog. However, because users gossip their local clicklogs in intervals to subsets of other users, it is entirely plausible that a node or subset of the network could be unaware of newly added items with matching metadata at

key	nodeID	term	ranked_results	clicked	tags
tuple	integer	string	list[integer]	integer	list[string]

the time of the query. If this were to occur, a user could click on a recommended item that contains no matching metadata to the search query, and then gossip their clicklog history to nearby nodes, who then also perform a search for the same term and click on the same result. Such an occurrence would then erroneously lead to a term-item pairing for which the associated item actually contains no matching metadata, which could then propagate throughout the network.

In order to avoid this situation, search results that contain matching metadata are always ranked above items that have term-item matches in the clicklog yet contain no matching metadata. The justification for such is that should users wish to find a specific item, they ostensibly are aware of the title, artist, album, or some other trait that would be found within the item's metadata such that they need not rely entirely upon the search history of a specific term in order to find said item. A positive side-effect of this restriction is that it also diminishes the effect of adversarial users "query-bombing" the network to negatively influence the performance of the ranking model.

### B. Clicklog Structure

Each node in the network contains a clicklog that stores the following information as a row entry: the node's unique ID, the query term, the query results in descending order, the item the user clicked on, the title of the item clicked upon, the tag metadata associated with that item, and a unique key associated with the query term consisting of the concatenation of the node's unique ID and the local query number. The key is used to determine the order of the clicklog without the need for timestamps, as timekeeping in a distributed system is a complex problem that is beyond the scope of this paper. When a query is performed, the results are stored locally in memory until a user clicks upon a result, after which the clicklog entry is created and appended locally. The gossiping node then samples at uniform random approximately 10% of its clicklog to gossip, dramatically reducing the size of the gossip message<sup>2</sup>, resulting in the linear growth of message space overhead. Over time, each node becomes increasingly aware of the click behavior of other nodes in the network without necessarily gleaning insight into the local libraries of said nodes. As such, the dissemination of clicklog data enables the unsupervised model to learn from the behavior of other users without revealing personally identifiable information (PII).

### C. Gossiping Clicklogs

The design of the gossip protocol that propagates clicklog information directly affects the performance of the ranking model, and therefore needs to be deliberately designed such that clicklog information is adequately disseminated without

<sup>2</sup>Each query results in approximately 600 bytes of clicklog data.

congesting the network. In order to determine exactly how the gossip parameters affect the model, specific evaluation metrics need to be determined. For example, should a node receive  $|K| = 10$  results for a specific query, it is important to determine how many of these results are in the "optimal" ranking, i.e. for each result  $k_i \in K$  the distance between the local rank  $L(k_i)$  in the above query versus the global average rank  $G(k_i)$  across all participants in the network for that query term. In this situation, an item with an "optimal" ranking has a distance of  $G(k_i) - L(k_i) = 0$  for any specific query.

In distributed and decentralized networks it is well-understood that obtaining a global "snapshot" of the current network state ranges from "trivial" for small networks to "intractable" for large global networks. Well-known algorithms such as Chandy-Lamport [26] are still imperfect as they fail to capture incipient changes to the network state deriving from messages that are currently underway during the time of the snapshot, such that by the time the algorithm terminates the state of the network may have already changed. As such, determining a global truth for a p2p network can only be easily performed in a contained simulation environment in which a global observer aggregates all changes to the network's state. Therefore, it must be understood that any comparisons against a "global" optimum in this experiment come with the caveat that in a live network the global optimum may not be feasibly observable.

### D. Node Discovery and Similarity Weighting

As nodes begin to receive new gossip messages, a brief pipeline extrapolates certain patterns from incoming data. After a gossip message is received by node  $n_i$ , it appends the new data to its existing clicklog and subsequently searches the incoming data for previously unseen unique node IDs. These unseen node IDs are added to a local list of known nodes, which are then sorted in descending order by the Jaccard similarity between their queries and the results they each click upon. The similarity score  $S$  between a pair of nodes  $n_i$  and  $n_j$  is calculated as follows:

- Find the intersection of query terms in the clicklog between  $n_i$  and  $n_j$ .
- Within this intersection, find all matching click results.
- For each node pair, the number of identical query-click pairs is divided by the overall number of query matches, resulting in a similarity ratio between 0.0 and 1.0, where 1.0 indicates that two nodes have clicked on the exact same item for every single matching query.

That is,

$$S_i(n_j) = \frac{|C_i(Q) \cap C_j(Q)|}{|C_i(Q) \cup C_j(Q)|}$$

where  $C_i(Q)$  indicates the set of items node  $n_i$  has clicked on for query  $Q$ . Therefore, the similarity is a ratio of identical query-click tuples to the overall number of queries shared between two nodes. As such, every node maintains a list of nodes it has become aware of via the clicklog, and

determines its similarity to other nodes based on past click behavior. This similarity is then used to weight the results of future queries based on the click behavior of other users, such that users are more likely to see results other similar users have clicked on for similar query terms.

In order to isolate highly irregular behavior, we introduce a binary normalization coefficient  $F$  to the user similarity score. When  $F = 0$ , only the clicklogs of adjacent nodes with  $S_i(n_j) > 0$  are considered when ranking results. When  $F = 1$ , a node considers the clicklogs of all nodes it has received gossip from when ranking query results. As such, this normalization parameter allows for nodes to discount the clicklogs of other nodes if these nodes have query and click behavior that does not match its own at least once.

Similarity weighting is calculated by taking the dot product between the aforementioned similarity scores for each node and sorted results based on the overall number of clicks found in each node’s local clicklog. The resulting ranking  $R$  provided to querying node  $n_i$  for query  $Q$  is therefore calculated as:

$$R_i(Q) = (\forall k \in K_Q), \sum_{j=0}^N (C_k \cdot (S_i(n_j) + F))$$

where  $S_i(n_j)$  indicates the similarity score for each node pair  $(n_i, n_j) \in N$ , and  $C_k$  indicates the number of clicks associated with item  $k \in K_Q$  where  $K_Q$  is the unsorted set of results for query  $Q$ . The resulting items are sorted in descending order by their associated scores. As such, each potential query result is assigned a score based on the number of clicks found in each node’s clicklog, weighted by the similarity of each node to the node performing the query. Therefore, the dissemination of clicklog data not only informs other nodes of the popularity of items, it also allows for nodes to cluster themselves based on an easy-to-compute metric, further allowing for personalization of results.

A drawback of introducing such a similarity metric into the ranked results is that it introduces a potential attack vector for adversaries to influence the results of future queries throughout the network, e.g. via spam or sybil attacks. Spam attacks become less viable as the number of legitimate users grows larger, while more targeted attacks may be thwarted by the user similarity scheme itself. An adversary attempting to undermine the ranking algorithm by intentionally selecting irrelevant results for specific queries would find themselves increasingly isolated from other users performing legitimate queries, as their behavior over time would continue to deviate from that of other users. Sophisticated adversaries would then need to mimic legitimate behavior for a large portion of their queries in order to remain relevant to other users without ostracizing themselves.

#### IV. DATASET AND EXPERIMENT SETUP

##### A. Dataset

The dataset utilized in this experiment was compiled from a series of 256 musical releases by real artists via the

PandaCD record label, all of which were released under the Creative Commons license. Entries may be singles, albums, EPs (extended-play releases), and LPs (limited-play releases). Every entry consists of three attributes: 'Title', 'Artist', and 'Album', as well as a number of associated 'Tags' as metadata, which describe the release in terms of genre. These tags have been compiled into a corpus of potential query terms, and every query term in this experiment consists of exactly one tag, of which there are a total of 39 unique tags.

##### B. Experiment Setup

Initially we conduct a baseline validation experiment to demonstrate the sensitivity of the node discovery process within distributed machine learning. Realistic simulations lack any centrality and thus have no central coordinator to discover other nodes. Our design integrates node discovery using the clicklog itself. Thus a single clicklog message provides both overlay network information for gossip dissemination, as well as the underlying data upon which the unsupervised model relies. This baseline experiment entails no adversarial interference, demonstrating how individual nodes adjust their rankings over time as they receive gossip throughout the simulation. All other experiments build upon this validation simulation’s setup for comparison purposes. Across all experiments, the simulated network consists of 100 nodes, all of which begin with a limited number of library items. The simulation is initialized as follows:

For each node  $n_i \in N, i = \{0, \dots, 99\}$  in the network,  $n_i$  is initialized by selecting at uniform random 10% of the items from the music dataset to add to its local library (approximately 26 songs per node). Next, a series of initial searches are performed. For each of the 39 possible query terms, each node performs a search for said query term and chooses at random one item from its library with a tag matching the query term (should it exist) and appends this entry to its local clicklog. Should a node’s library not contain any items with tags matching the query term, it selects at random a single item from its local library, thereby introducing a small degree of noise into the clicklog. At this point, no ranking or click modeling is utilized for selection, and the clicklog of node  $n_i$  contains exactly 39 items. Then,  $n_i$  gossips a random sample of 10% of its local clicklog to a randomly selected node  $n_j \in \{n_0, \dots, n_i\}$  such that each node contains no more than 44 clicklog entries - 39 belonging to itself, and up to an additional five items that it receives via gossip from another peer.

This method of initialization affords each peer in the network an even number of clicklog items to utilize during a query, but an uneven distribution of network knowledge across each node such that nodes with higher IDs are more likely to be aware of a higher number of peers at the outset of the simulation. After every node has been initialized, the simulation begins and nodes are chosen uniformly at random alongside a random query term from the corpus to perform a query-term search. The results of the search are ranked as detailed in Section 2A, and an item to be clicked upon

is chosen based on the aforementioned click model. The search and click results are then appended to this node’s local clicklog. Thereafter, this node then performs a gossip round by randomly selecting a subset of peers it is aware of (except in the case of the *Push vs. Pull* experiments, see Section 5D), equal to 10% of the nodes it is aware of (up to a maximum of 10 targets).

There are two popular schemes for initiating gossip in p2p networks: time-based and probabilistic. In time-based schemes, a node gossips every  $t$  time units, whereas in most probabilistic schemes any given node has a probability  $p$  per time unit to gossip some information to a subset of other nodes, such that after  $t$  time units there is a

$$\Pr(X = t) = (1 - p)^{t-1} \cdot p$$

probability that a node will have gossiped. To clearly illuminate the effect of adversaries on G-Rank’s performance, our experiment implements a hybrid gossip approach such that at every simulation tick  $t$  a random node performs a query and then gossips its clicklog to every node it is aware of (see Section 3C). As such, a node is guaranteed to gossip post-query yet still is chosen probabilistically such that the above geometric probability distribution holds, given that a node has probability  $p = \frac{1}{|N|}$  of performing a query-then-gossip operation at an arbitrary time step  $t$ . By utilizing such a gossip mechanism we ensure that clicklog information is propagated regularly throughout each simulation.

### C. Click Modeling

Modeling realistic user-clicking behavior is essential to the development of ranking algorithms. Not all user clicks may be on relevant items in a list, and as such it can be expected that a certain degree of noise exists in user click data. Extrapolating such noise into a simulation therefore requires careful consideration. Without anticipating and modeling a certain degree of noise, a ranking model’s query results may erroneously converge towards irrelevant items. Anticipating and modeling noise in user click behavior has been investigated [16], however for this experiment users select the highest-ranking item in most queries, except when multiple results with equal relevance scores were shown to the user. In this case, the result with the lowest ID was chosen as a tiebreaker.

## V. ADVERSARIAL SIMULATIONS AND PERFORMANCE ANALYSIS

For all experiments we conducted an *evaluation round* every 100 queries, where a number of performance metrics are gathered (see Section 5E). In addition to the regular performance evaluation, these evaluation rounds act as progress markers at discrete intervals in the simulation, which are discussed in Section 5F. Each experiment, including the baseline, was conducted twice: once with similarity weighted normalization coefficient  $F = 0$  and again with  $F = 1$ , demonstrating the effect that cluster isolation (see Section 3D) has on G-Ranks performance. Unless stated otherwise, simulation parameters are as follows:

- When gossiping, each node targets 10% of the nodes it is aware of (up to a maximum of 10 recipients) all of whom are drawn from local knowledge via the clicklog.
- Gossip messages include a random uniform sampling of 10% of the local clicklog. For clicklogs with fewer than 10 entries, exactly one clicklog item is shared via gossip.
- When a new node joins the network, it is bootstrapped by a randomly selected node. This bootstrap node gossips exactly as described in the previous point, affording the new node a selection of clicklog items to work with. Via this bootstrap mechanism, each adversarial node becomes aware of a handful of other nodes in the network to which it can gossip during its attack phase.
- There are exactly 10 malicious nodes in each adversarial experiment, which are bootstrapped as stated above at simulation time step  $t = 2000$ , exactly 20% through the experiment. The time of attack is indicated by a red vertical line in each figure.

### A. Baseline Experiment

We simulate several adversarial conditions alongside two "baseline" simulations with no adversaries. Each adversarial simulation is intended to isolate and investigate the effects of specific adversarial and anti-social behavior on G-Rank’s performance. Each simulation’s results is compared to the baseline global performance of G-Rank, as the global optimal rankings are negatively affected by such attacks. As such, each scenario’s impact on G-Rank’s ability to converge towards a true global optimality without adversarial interference is investigated with the aid of the metrics described in Section 4B.

### B. Targeted Sybil Attack

The first adversarial simulation implements a basic sybil attack where five new sybil nodes are bootstrapped into the network as described above. Each sybil attacker chooses a single specific term to perform 100 queries with, each time clicking the bottom-most item in the list of ranked results. After the series of queries are complete, the attackers gossip their entire clicklog to every node they have become aware of during their bootstrap phase as if it were legitimate clicklog gossip. This attack artificially inflates the relevance score of otherwise low-ranked results, undermining the veracity of the rankings other nodes are shown. By repeatedly choosing the lowest-ranked item in the list, the attacker attempts to usurp G-Rank’s ability to determine the most popular item associated with the query term. Such an attack is performed to demonstrate how a sophisticated adversary could ostensibly undermine a p2p network utilizing G-Rank by forcing their desired results towards the top of query results.

### C. Clicklog Inflation Attack

The second adversarial simulation differs from the previous in two ways: the number of queries each adversary performs 1000 queries instead of 100, and each adversary

chooses results purely at random. By performing a significant number of queries before gossiping the entirety of its clicklog, the adversary attempts to undermine G-Rank via the dramatic inflation in size of non-adversarial node clicklogs. The propagation of random clicklog noise throughout the network is investigated against the more targeted sybil attack mentioned previously. In large decentralized p2p networks it is highly unlikely that any single node is aware of all other nodes in the network. As such, the clicklog inflation attack is most likely to have the greatest impact upon the initial recipients of adversarial gossip due to the fact that benign nodes gossip only a portion of their local clicklogs at any given time, limiting the contagion.

#### D. Push vs. Pull Experiment

##### TODO: flesh this out

Within this fourth experiment we introduce a number of malicious nodes which conduct a Sybil attack. This experiment shows the dramatic impact of push versus pull gossip. This experiment proves that it is vital for security that malicious nodes can not easily insert their polluting content with honest peers, *i.e.* a push architecture. With a pull architecture, peers are more autonomous and decide individually the speed of incoming information, if they trust another peer, or may randomly sample from discovered peers. Malicious nodes in this experiment try to push two messages when gossiping. With the pull architecture, only one message per gossip phase is accepted. As Internet bandwidth is cheap, this simple experiment shows a first line of defence against clicklog spam without the need for significantly modifying G-Rank’s core functionality.

#### E. Evaluation Metrics

For each simulation we utilized a number of metrics to evaluate G-Rank’s ranking performance over time, its tenacity when facing adversarial conditions, and its computational performance over time. The primary performance metric utilized is a positional edit distance metric where we compare the sum of index distances between each unique element in  $R_i(Q)$  and  $R_g(Q)$ , where  $R_g(Q)$  indicates the globally optimal ranking for query  $Q$ .  $R_g(Q)$  is computed simply by ranking the most popular items by their respective number of clicks associated with a specific query term across all nodes<sup>3</sup>. This metric allows us to determine how far each item is from its most optimal position at any given point in time, giving us the ability to determine how G-Rank performs for any given node for a specific query term.

We also consider the rate of convergence towards optimality - that is, the velocity of G-Rank’s convergence towards the global optimal across all nodes and possible query terms over time, measured in the above distance metric. The rate of change in this distance metric affords us insight into G-Rank’s behavior over time, particularly during the adversarial simulations, such that we can better understand how G-Rank’s long-term performance is affected by transient

<sup>3</sup>This information is unavailable to individual nodes at runtime, and is only observable during simulation.

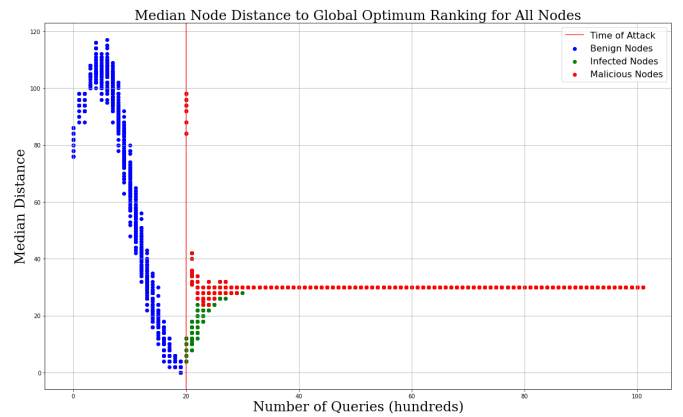

Fig. 2. Targeted Sybil Attack: The median distance to the optimal ranking for each node, across all possible query terms. Post-attack, non-malicious nodes converge higher towards an equilibrium.

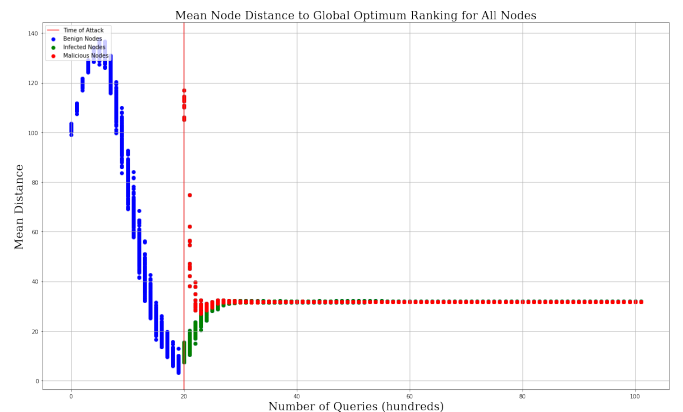

Fig. 3. Targeted Sybil Attack: The mean distance to the optimal ranking for each node, across all possible query terms.

adversarial events. For each arbitrary query term, we also measure the number of results containing the most popular result (globally) in the top position in order to demonstrate the roughly even distribution of performance, regardless of the frequency a specific query term is issued. (TODO: Bad description, can I do better?)

In terms of space and storage metrics, we also measure the average clicklog size across all nodes over time, as gossip occurs consistently yet as time goes on the number of duplicate clicklog items being shared likely continues to grow. To better understand G-Rank’s dependence upon gossip, we monitor the rate of growth in gossip message size (in bytes) as individual clicklogs grow large - an important metric considering the potential variation in each node’s processing power and storage space. However, we do not consider any time-based computational overhead metrics as these are highly dependent upon the programming language in which G-Rank is implemented as well as each individual device’s computational power.

#### F. Performance Analysis

The results of the initial baseline experiment show that without any adversarial conditions the performance of G-

Rank approaches the globally-optimal ranking for each node. **FIGURE X** shows that the distance between each node's local ranking of results and the globally optimal ranking for each possible query term drops dramatically after just a few evaluation rounds. **FIGURE X** shows that the percentage of queries containing the most popular song per tag grows logarithmically, further indicating that early gossip rounds have a profound effect on improving search results. As more gossip occurs, the number of queries containing the top song associated with each query approaches 100%, as seen in **FIGURE X**. Figure 2 also shows how the number of most popular songs associated with each possible query term grows at approximately even rates, indicating that the gossip scheme itself does not lead to an imbalance in query term searches.

Considering the known threat that sybil and spam attacks pose to p2p networks, the results of the adversarial simulations generally fall in line with expectations. G-Rank is susceptible to sybil and spam attacks, though its ability to recover post-attack and continue converging towards global optimality is notable. However, clicklog inflation attacks have a diminished effect, with the majority of the impact affecting the immediate recipients of malicious gossip. This indicates that mechanisms that mitigate or prevent the propagation of messages throughout the network outside of explicitly-designated gossip messages may greatly diminish negative consequences of spam and sybil attacks.

As seen in **FIGURES X, Y, and Z**, G-Rank is able to begin re-converging towards the global optimum, albeit more slowly in the the Clicklog Inflation attack. This is likely due to the significant increase in clicklog size, meaning that a significant number of benign clicklog entries are required post-attack to offset the effect of malicious clicklog entries. **FIGURE X** shows that when  $F = 0$ , benign users are not as dramatically affected by malicious gossip, particularly during the clicklog inflation attack. However, **FIGURE X** shows that the targeted sybil attack can dramatically affect the unfortunate recipients of malicious gossip, particularly in the immediate aftermath of receiving such gossip. This suggests that the length and diversity of each individual node's clicklog has an effect on an adversary's ability to sabotage G-Rank. As the simulation time increases, the average local clicklog length also grows (as seen in **FIGURE X**), affording nodes the opportunity to calculate similarity metrics with an increasingly large subset of other nodes.

The effect of the normalization coefficient  $F$  is noticeable, yet has varied effect depending upon the type of attack it faces. Setting  $F = 0$  has the consequence of effectively disqualifying any nodes without at least one matching query-click pair with the querying node, which thereby has the knock-on effect of dramatically reducing the probability that an adversary's behavior influences any ranked results. Any influence an adversary then has on ranking is dependent upon the number of matching query-click pairs, which favors non-targeted attacks such as the clicklog inflation attack.

Conversely, when  $F > 0$ , all clicklog data (including malicious entries) is considered in the ranking process as

the weight of each entry will subsequently also be a positive non-zero value. The positive effect this has is greater personalization results for benign queries; clicklog results from nodes with similarity scores  $S_i(n_j) = 0$  will still have the number of clicks associated with that result considered in the final ranking. The negative effect is that all clicklog entries, including malicious entries, will be considered. **FIGURES X and Y** demonstrates the difference in effect between two identical simulation environments where  $F = 0$  and  $F = 1$ . As seen in these figures, the normalization constant affords benign queries closer convergence to global optimum at the expense of dramatically reduced resilience in the face of attack.

### G. Future Work

**(TODO: In progress...)**

Potential for future development of unsupervised decentralized search and ranking models in p2p networks is exceptionally rich. G-Rank demonstrates that a simple unsupervised model can recommend near-perfect results to users in sterile network conditions. One of the primary pitfalls of such unsupervised methods is mitigating the threat adversarial actors such as sybil attackers may have on the model. G-Rank is capable of recovering and improving performance after a singular sybil attack, but cannot adapt under consistent and persistent sybil attacks. As such, mitigating threats above the network and protocol layers at the model level is a rich field for future development.

Potential model improvements may include augmenting the user clustering model beyond a simple similarity metric, such that sybil and other spam attacks become classified as outliers with regards to "typical" user behavior, such that recommendation and ranking scores become based off of behavior of other users within clusters.

## VI. CONCLUSION

**(TODO: In progress...)**

The results demonstrate that unsupervised search-and-rank models designed specifically for p2p applications show merit and are worthy of further research. Relatively basic unsupervised methods such as G-Rank are capable of converging towards a global optimum, even when provided with limited data. G-Rank shows notable resilience in the fact of transient adversarial conditions, particularly regarding targeted nefarious behavior. The impact of spam attacks depends heavily upon the clicklog dissemination gossip scheme, such that spam mitigation methods implemented between the network and application layers may dramatically reduce the negative impacts of such attacks. Another area worthy of further research is spam mitigation within the unsupervised model itself, particularly with regards to outlier detection in clicklog data.
